Public health authorities in Brazil are currently investigating whether the apparent surge in the number of babies born with microcephaly are causally linked with Zika virus (ZIKV) infection during pregnancy. Indeed, by 2015 an increase in the number of infants born with microcephaly was reported in Brazil, a country experiencing since April 2015 the largest known outbreak of ZIKV infection (Petersen et al., 2016). The number of suspected cases of microcephaly has continued to rise in Brazil reaching about 5000 cases since the authorities began investigating the surge. The World Health Organization Emergency Committee on ZIKV stated that a causal link between ZIKV and microcephaly is “strongly suspected, though not yet scientifically proven” (WHO, 2016a) and declared the cluster of microcephaly cases and other neurological disorders reported in Brazil as a Public Health Emergency of International concern (WHO, 2016b). After the suspicion was raised that the increase in birth defects could be attributed to the massive use of the larvicide pyriproxifen, Brazil’s health ministry quickly posted a clarification on the use of pyriproxifen, noting that there is no scientific basis for a link between the use of the larvicide and microcephaly and that some cities that have not used it have also reported microcephaly cases. This temporal increase in cases of microcephaly could also be distorted given both raised awareness and changing definitions of microcephaly over time (Victora et al., 2016). In fact, out of the 4783 suspect cases of microcephaly reported, only 1103 had complete clinical, laboratory and imaging examinations and 404 of them were classified as confirmed cases of microcephaly: brain abnormalities were detected by imaging in 387 babies and ZIKV was detected in 17 babies, including two fetal losses (Victora et al., 2016).

Although the findings can at least in part be an overestimation due to diagnostic bias, there has been a huge increase in congenital microcephaly from fewer than 150 cases reported in the country in 2014, and it looks temporally related to the introduction and widespread dissemination of ZIKV infection. Epidemiological investigations are ongoing to assess the degree of association between the infection and microcephaly.

What is microcephaly?

Microcephaly is a neonatal malformation defined as a head size much smaller than those of other babies of the same age and sex. If this combines with poor brain growth, babies with microcephaly may achieve developmental disabilities. The clinical presentation of microcephaly ranges from mild to severe. There are no specific tests to determine if a baby will be born with microcephaly, but ultrasound scans in the third trimester of pregnancy can sometimes identify the problem (CIDRAP 2016, WHO 2016b). Microcephaly can result from chromosomal abnormalities, exposure to drugs, alcohol, other environmental toxins, premature fusion of the bones of the skull (craniosynostosis), certain metabolic disorders, and congenital infections (Schuler-Faccini et al., 2016).

One of the causes of microcephaly involves abnormal function of centrosomes (Thornton et al., 2009), normally associated with mitosis, but also involved in other cellular processes including migration, polarity and proper trafficking of vesicles. Amplification of the number of centrosomes has been revealed to be one of the inducers of microcephaly (Marthiens et al., 2013). In fact, in the context of neural brain development, an increase in centrosomes in mice results in delayed mitosis, increased apoptosis, improper neural stem cell orientation, premature neuronal differentiation, and a decreased number of progenitor cells (Marthiens et al., 2013). The overall effect is reduced brain matter formation, ultimately leading to reduced brain size.

Other viruses and microcephaly

During human gestation, viruses can cause intrauterine infections associated with pregnancy complications and fetal abnormalities. Common sonographic abnormalities may be indicative of fetal viral infections. Some of the pathognomonic sonographic findings enable diagnosis of a specific congenital syndrome, e.g. ventriculomegaly and intracranial and hepatic calcifications in cytomegalovirus...
The Zika virus

ZIKV is a single stranded RNA arbovirus member of the genus Flavivirus and is related to other mosquito-borne viruses such as Dengue, Yellow Fever, Japanese encephalitis and West Nile Fever viruses. Transmission of ZIKV between humans occurs primarily through the bite of an infected female mosquito of the Aedes species. Apart from the mosquito-originated inoculation, transmission of ZIKV has been reported to occur via sexual intercourse and blood transfusion; vertical perinatal transmission has also been reported (Petersen et al., 2016).

The Zika virus and microcephaly

Like CMV, ZIKV may have the potential to infect the fetus and cause neurodevelopmental dysfunctions including microcephaly. On 17 November 2015, the Brazilian ministry of health reported the presence of ZIKV RNA in amniotic fluid samples collected from two pregnant women from the state of Paraiba, whose fetuses showed microcephaly. The two mothers had symptoms compatible with ZIKV disease at gestation weeks 18 and 19. Ultrasonography done at gestation week 20 revealed calcifications in the fetuses’ brains, and repeated scan at gestation week 28 confirmed the diagnosis of microcephaly. Urine and serum samples from the mothers were negative for ZIKV genome detection at gestation week 28, but amniocenteses were positive with a viral load 10,000 times higher than that normally found in blood from adults with acute infection and exanthema (ECDC 2015). In December 2015, the Brazilian ministry of health reported the presence of ZIKV genome in the blood and tissue samples of a baby from the state of Pará with microcephaly.

Pathogenetic hypothesis for microcephaly related to Zika virus

In 1952, Dick et al., (Dick et al., 1952, Dick 1952) demonstrated ZIKV tropism for the brain in intraperitoneally infected mice. About 20 years later central nervous system disease was observed in infected mice by Bell et al. (Bell et al., 1971). The virus could cross the blood brain barrier and infected both neurons and glia, producing a variety of intracytoplasmic inclusions, which they termed, “virus factories”. These factories originated from the endoplasmic reticulum and associated with other organelles including the nucleus and the mitochondria. Those microscopic observations are also compatible with the induction of autophagy. This is not unexpected, as the induction of autophagy has been observed for other flaviviruses, as a result of the interaction between the virus and the endoplasmic reticulum (Blazquez et al., 2014).

More recently, a potential role for autophagy in ZIKV infection has been shown in cultured human skin cells, where the formation of autophagosomes containing viral capsids was observed (Hamel et al., 2015). This event seems to be relevant for viral replication, as the pharmacological modulation of autophagy might decrease the amount of viral RNA produced in the cultures. Although autophagy has not been described in Zika-infected neural cells, the evidence obtained in experimentally-infected skin fibroblasts (Hamel et al., 2015) opens a new landscape on the mechanisms of generation of brain microcephaly. Urine and serum samples from the mothers were negative for ZIKV genome detection at gestation week 28, but amniocenteses were positive with a viral load 10,000 times higher than that normally found in blood from adults with acute infection and exanthema (ECDC 2015). In December 2015, the Brazilian ministry of health reported the presence of ZIKV genome in the blood and tissue samples of a baby from the state of Pará with microcephaly.

Pathogenetic hypothesis for microcephaly related to Zika virus

Although autophagy has not been described in Zika-infected neural cells, the evidence obtained in experimentally-infected skin fibroblasts (Hamel et al., 2015) opens a new landscape on the mechanisms of generation of brain microcephaly.
abnormalities, possibly mediated by the viral interference with the physiological process of autophagy. In fact, it is well known that the blockade of autophagy during embryogenesis leads to nervous system defects (Fimia et al., 2007). This provides some evidence to support the involvement of ZIKV in the damage of cells from multiple lineages, including neural cells (Bell et al., 1971).

Besides perturbation of the autophagy pathway, a summary of pathogenetic mechanisms involved in the generation of microcephaly is reported in the section “What is microcephaly?” Although the mechanisms of ZIKV pathogenesis appear to fall in line with the requirements for centrosome abnormalities, there is as yet no evidence to prove culpability.

Future studies need to be performed to definitively establish this link. In particular, vertical transmission of ZIKV as well as any direct or indirect effects of infection on neural development need to be concretely demonstrated. Furthermore, studies should explore other aberrations in fetal development apart from microcephaly.

Final comments

The ZIKV outbreak in the Americas and the South Pacific region is rapidly evolving, and a major concern is that its spread is likely to continue, as the vector species <i>Aedes aegypti</i> and <i>Aedes albopictus</i> are widely distributed there. Another concern is the possible spread of the epidemic out of these areas through autochthonous transmission, subsequent to the introduction of cases in European areas where the competent vector is present. <i>Aedes albopictus</i> is widely distributed in the Mediterranean basin including Italy.

Although it has not yet been confirmed that the population of mosquitoes living in Europe can effectively transmit the infection, an effective autochthonous transmission of an arbovirus (Chikungunya virus) sustained by <i>Aedes</i> mosquitos already occurred in Italy in 2007 (Bordi et al., 2008).

The return of travelers from ZIKV endemic areas may be a source for autochthonous transmission, especially in the months of increased mosquito activity. Enhanced surveillance and reporting of cases in these regions is recommended (ECDC 2016).

While a significant increase in the number of newborns presenting with a low head circumference seems established in the north-eastern states of Brazil, the magnitude of the increase cannot be precisely estimated. Although the microcephaly cases in Brazil seem to be spatio-temporally associated with the ZIKV outbreak, more robust investigations and research are needed to better understand this potential link. Furthermore dedicated studies, including case-control studies, are also needed to determine the magnitude of the potential risk and identify other possible risk factors.

In the meanwhile, appropriate information should be given to pregnant women traveling in endemic areas about their risk and about the correct diagnostic procedures and surveillance protocols. For the same reason, it is important to advise pregnant women, or women who are planning a pregnancy, to precautionally consider postponing travel to endemic areas. Moreover, some reports strongly support the possibility of transmission through sexual intercourse and blood transfusion (Petersen et al., 2016): therefore, it is also important to inform patients, even with low-grade symptoms, to use condoms in sexual intercourse and to avoid blood donations. Similarly, travellers to endemic areas should be informed about these routes of transmission, in order to reduce at-risk behaviours.
